EXECUTIVE SUMMARY

The Bristol Bay watershed in southwestern Alaska supports the largest sockeye salmon fishery in the world, is home to 25 federally recognized tribal governments, and contains large mineral resources. The potential for large-scale mining activities in the watershed has raised concerns about the impact of mining on the sustainability of Bristol Bay's world-class commercial, recreational, and subsistence fisheries and the future of Alaska Natives tribes in the watershed, who have maintained a salmon-based culture and subsistence-based way of life for at least 4,000 years.

The U.S. Environmental Protection Agency (USEPA) launched this assessment to determine the significance of Bristol Bay’s ecological resources and evaluate the impacts of large-scale mining on these resources. It uses the well-established methodology of an ecological risk assessment, which is a type of scientific investigation that provides technical information and analyses to foster public understanding and to inform future decision making. As a scientific assessment, it does not discuss or recommend policy, legal, or regulatory decisions, nor does it outline or analyze options for future decisions.

The purpose of the assessment is to characterize the biological and mineral resources of the Bristol Bay watershed, increase understanding of the impacts of large-scale mining on the region’s fish resources, and inform future government decisions related to protecting and maintaining the physical, chemical, and biological integrity of the watershed.

The assessment is intended to be a technical resource for the public and for federal, state, and tribal government entities as they consider how best to address the challenges of mining and ecological protection in the Bristol Bay watershed. It will inform the ongoing discussions of the risks of mine development to the sustainability of the Bristol Bay salmon fisheries and thus will be of value to the many stakeholders in this debate.

The assessment also could inform the consideration of options for future action by government bodies. This includes USEPA, which has been petitioned by multiple groups to address mining activity in the Bristol Bay watershed using its authority under the Clean Water Act (CWA). Should specific mine
projects reach the permitting stage, the assessment will enable state or federal permitting authorities to make informed decisions to grant, deny, or condition permits and/or conduct additional research or assessment as a basis for such decisions. USEPA is conducting this assessment consistent with its authority under the CWA Section 104(a) and (b).

**Scope of the Assessment**

This assessment reviews, analyzes, and synthesizes information relevant to impacts of large-scale mine development on Bristol Bay fisheries and subsequent effects on the wildlife and Alaska Native cultures of the region. Given the economic, ecological, and cultural importance of the region's salmonids (sockeye, Chinook, coho, chum, and pink salmon, as well as rainbow trout and Dolly Varden) and the concern of stakeholders and the public that a mine could affect those species, the primary focus of the assessment is the abundance, productivity, and diversity of these fishes. Because wildlife and Alaska Native cultures in Bristol Bay are intimately connected to and dependent upon these and other fishes, changes in these fisheries are likely to affect the abundance and health of wildlife populations and the viability and welfare of Alaska Native populations. Therefore, wildlife and Alaska native cultures are also considered as assessment endpoints, but only as affected by changes in salmonid fisheries.

The assessment considers multiple spatial scales. The largest scale is the Bristol Bay watershed, which is a largely undisturbed region with outstanding natural, cultural, and mineral resources. Within the larger Bristol Bay watershed, the assessment focuses on the Nushagak and Kvichak River watersheds (Figure ES-1). These are the largest of the Bristol Bay watershed's six major river basins, containing about 50% of the total watershed area and are identified as mineral development areas by the State of Alaska. The Pebble deposit, the most likely site for near-term, large-scale mine development in the region, is located in the headwaters of tributaries to both the Nushagak and Kvichak Rivers. Therefore, both of these watersheds are subject to potential risks from mining. The third spatial scale is the watersheds of the three tributaries that originate within the potential footprint of a mine on the Pebble deposit: the South Fork Koktuli River, which drains the Pebble deposit area and converges with the North Fork west of the Pebble deposit; the North Fork Koktuli River, located to the northwest of the Pebble deposit, which flows into the Nushagak River via the Mulchatna River; and Upper Talarik Creek, which drains the eastern portion of the Pebble deposit and flows into the Kvichak River via Iliamna Lake, the largest undeveloped lake in the United States (Figure ES-1). The mine footprints under the three realistic mine scenarios evaluated in the assessment make up the fourth spatial scale. These scenarios—Pebble 0.25, Pebble 2.0, and Pebble 6.5—define three potential mine sizes, representing different stages in the potential process of mining the Pebble deposit. The final spatial scale is the combined area of the subwatersheds between the mine footprints and the Kvichak River watershed boundary that would be crossed by a transportation corridor linking the mine site to Cook Inlet.
Figure ES 1. The Nushagak and Kvichak River watersheds of Bristol Bay.
The assessment also addresses two periods for mine activities. The first is the development and operation phase, during which mine infrastructure would be built and the mine would be operated. This phase may last from 20 to 100 years or more. The second is the post-mining or post-closure phase, during which the site would be monitored. As necessary, water treatment and other waste management activities would continue and any failures would be remediated. Because mine wastes would be persistent, this period could continue for centuries and potentially in perpetuity.

We began the assessment with a thorough review of what is known about the Bristol Bay watershed, its fisheries and wildlife populations, and its Alaska Native cultures. We also reviewed information about copper mining and publicly available information outlining proposed mining operations for the Pebble deposit, which has been the focus of much exploratory study and has received much attention from groups in and outside of Alaska. With the help of regional stakeholders, we developed a set of conceptual models to show potential associations between salmon populations and the environmental stressors that might reasonably be expected as a result of large-scale mining. Then, following the USEPA's ecological risk assessment framework, we analyzed the sources and exposures that could occur and the potential responses to those exposures. Finally, we characterized the risks to fish habitats, salmon, and other fish populations; and the implications of those risks to the wildlife and Alaska Native cultures that use them.

This is not an in-depth assessment of a specific mine, but rather an examination of impacts of reasonably foreseeable mining activities in the Bristol Bay region, given the nature of the watershed’s mineral deposits and the requirements for successful mine development. The assessment analyzes mine scenarios that reflect the expected characteristics of mine operations at the Pebble deposit. It is intended to provide a baseline for understanding the impacts of mine development not just at the Pebble deposit, but throughout the Nushagak and Kvichak River watersheds. The mining of other existing porphyry copper deposits in the region would likely include the same types of mining activities and facilities evaluated in this assessment for the Pebble deposit (open pit mining, waste rock piles, tailings storage facilities [TSFs]), and therefore would present potential risks similar to those outlined in this assessment. However, those mines would likely be most similar to the smallest of the mine scenarios analyzed in this assessment (Pebble 0.25), because the other ore bodies are believed to be much smaller than the Pebble deposit.

This assessment does not consider all impacts associated with future large-scale mining in the Bristol Bay watershed. Although the mine scenarios assume development of a deep-water port on Cook Inlet to ship product concentrate elsewhere for smelting and refining, impacts of port development and operation are not assessed. The assessment does not evaluate impacts of the one or more large-capacity, electricity-generating power plants that would be required to power the mine and the port. It also does not assess the effects of induced development that could result from large-scale mining in the region. However, it is recognized that a large-scale mine development could induce the development of additional support services for mine employees and their families, recreational facilities due to increased access, vacation homes, and transportation infrastructure beyond the main corridor (i.e., airports, docks, and roads).
Ecological Resources

The Bristol Bay watershed provides habitat for numerous animal species, including 29 fish species, more than 40 terrestrial mammal species, and more than 190 bird species. Many of these species are essential to the structure and function of the region’s ecosystems and economies. Chief among these resources are world-class commercial and sport fisheries for Pacific salmon and other salmonids. The watershed supports production of all five species of Pacific salmon found in North America: sockeye (*Oncorhynchus nerka*), coho (*O. kisutch*), Chinook (*O. tshawytscha*), chum (*O. keta*), and pink (*O. gorbuscha*) (Figure ES-2). Because no hatchery fish are raised or released in the watershed, Bristol Bay’s salmon populations are entirely wild. These fishes are anadromous, meaning that they hatch and rear in freshwater systems, migrate to sea to grow to adult size, and return to freshwater systems to spawn and die.

The most abundant salmon species in the Bristol Bay watershed is sockeye salmon. The watershed supports the largest sockeye salmon fishery in the world, with approximately 46% of the average global abundance of wild sockeye salmon (Figure ES-3). Between 1990 and 2009, the annual average inshore run of sockeye salmon in Bristol Bay was approximately 37.5 million fish. Annual commercial harvest of sockeye over this same period averaged 25.7 million fish. Approximately half of the Bristol Bay sockeye salmon production is from the Nushagak and Kvichak River watersheds, the main area of focus for this assessment (Figure ES-3).

Chinook salmon are also abundant in the region. Chinook returns to the Nushagak River are consistently greater than 100,000 fish per year and have exceeded 200,000 fish in 11 years between 1966 and 2010, frequently placing Nushagak River Chinook runs at or near the world’s largest. This is noteworthy given the Nushagak River’s small watershed compared to other Chinook-producing rivers such as the Yukon River, which spans Alaska, and the Kuskokwim River in southwestern Alaska, just north of Bristol Bay.

The Bristol Bay watershed also supports populations of non-salmon fishes that typically (but not always) remain in the watershed’s freshwater habitats throughout their life cycles. The region contains highly productive waters for sport and subsistence fish species, including rainbow trout (*O. mykiss*), Dolly Varden (*Salvelinus malma*), Arctic char (*S. alpinus*), lake trout (*S. namaycush*), Arctic grayling (*Thymallus arcticus*), northern pike (*Esox lucius*), and humpback whitefish (*Coregonus pidschian*). These fishes occupy a variety of habitats in the watershed, from headwater streams to wetlands to large rivers and lakes. The Bristol Bay region is especially renowned for the abundance and size of its rainbow trout: between 2003 and 2007, an estimated 183,000 rainbow trout were caught in the Bristol Bay Management Area.
Figure ES 2. Reported salmon (sockeye, Chinook, coho, pink, and chum combined) distribution in the South and North Fork Koktuli Rivers and Upper Talarik Creek watersheds. Designation of species spawning, rearing, and presence is based on the Anadromous Waters Catalog. Life stage specific reach designations are likely underestimates, given the challenges inherent in surveying all streams that may support life stage use throughout the year.
Figure ES 3. Total sockeye salmon run sizes by (A) region and (B) watershed in the Bristol Bay region. Values are averages from 1956 to 2005 and 1956 to 2010 for A and B, respectively.
The exceptional quality of the Bristol Bay watershed's fish populations can be attributed to several factors, the most important of which is the watershed's high-quality, diverse aquatic habitats, which are untouched by human-engineered structures and flow management controls. Surface and subsurface waters are highly connected, enabling hydrologic and biochemical connectivity between wetlands, ponds, streams, and rivers, thus increasing the diversity and stability of habitats able to support fish. These factors all contribute to making the Bristol Bay watershed a highly productive system. High aquatic habitat diversity also has supported the high genetic diversity of fish populations. This diversity in genetics, life history, and habitat acts to reduce year-to-year variability in total production and increase the stability of the fishery.

The return of spawning salmon from the Pacific Ocean brings marine-derived nutrients into the watershed and fuels terrestrial and aquatic food webs. Thus, the condition of Bristol Bay’s terrestrial ecosystems is intimately linked to the condition of salmon populations as well as to almost totally undisturbed habitats. The watershed continues to support large carnivores such as brown bears (Ursus arctos), bald eagles (Haliaeetus leucocephalus), and gray wolves (Canis lupus); ungulates such as moose (Alces alces gigas) and caribou (Rangifer tarandus granti); and numerous waterfowl species. Brown bears are abundant in the Nushagak and Kvichak River watersheds. Moose also are abundant, with populations especially high in the Nushagak River watershed where felt-leaf willow, a preferred forage species, is plentiful. The Nushagak and Kvichak River watersheds are used by caribou, primarily the Mulchatna caribou herd. This herd ranges widely through these watersheds, but also spends considerable time in other watersheds.

Alaska Native Cultures

The predominant Alaska Native cultures present in the Nushagak and Kvichak River watersheds—the Yup’ik and Dena’ina—are two of the last intact, sustainable, salmon-based cultures in the world. In contrast, other Pacific Northwest salmon-based cultures are severely threatened by development, degraded natural resources, and declining salmon resources. Salmon are integral to the entire way of life in these cultures as subsistence food and subsistence-based livelihoods, and are an important foundation for language, spirituality, and social structure. The cultures have a strong connection to the landscape and its resources. In the Bristol Bay watershed, this connection has been maintained for at least the past 4,000 years and is in part both due to and responsible for the continued undisturbed condition of the region’s landscape and biological resources. The respect and importance given salmon and other wildlife, along with the traditional knowledge of the environment, have produced a sustainable subsistence-based economy. This subsistence-based way of life is a key element of Alaska Native identity and serves a wide range of economic, social, and cultural functions in Yup’ik and Dena’ina societies.

Fourteen of Bristol Bay’s 25 villages and communities are within the Nushagak and Kvichak River watersheds, with a total population of 4,337 in 2010. Thirteen of the 14 communities have federally recognized tribal governments and a majority Alaska Native population. Many of the non-Alaska Native
residents in the watersheds also have strong cultural ties to the region and practice a subsistence way of life. In the Bristol Bay region, salmon constitute approximately 52% of the subsistence harvest, and for some communities this proportion is substantially higher.

The subsistence way of life in many Alaska Native villages is augmented with activities supporting cash economy transactions. Alaska Native villages, in partnership with Alaska Native corporations and other business interests, are considering a variety of economic development opportunities. Some Alaska Native villages have decided that large-scale hard rock mining is not the direction they would like to go in, while a few others are seriously considering this opportunity. All are concerned with the long-term sustainability of their communities.

Economics of Ecological Resources

The Bristol Bay watershed supports several economic sectors that are wilderness-compatible and sustainable: commercial, sport, and subsistence fishing; sport and subsistence hunting; and non-consumptive recreation. Considering all these sectors, the ecological resources of the Bristol Bay watershed generated nearly $480 million in direct economic expenditures and sales in 2009, and provided employment for over 14,000 full- and part-time workers. The Bristol Bay commercial salmon fishery generates the largest component of economic activity: it was valued at approximately $300 million in 2009 (sales from fishers to processors), and provided employment for over 11,000 full- and part-time workers at the season’s peak. These estimates do not include retail expenditures from national and international sales. The Bristol Bay sport-fishing industry supports approximately 29,000 sport-fishing trips, generates approximately $60 million per year, and directly employs over 800 full- and part-time workers (based on 2009 data). Sport hunting—mostly of caribou, moose, and brown bear—generates more than $8 million per year and employs over 100 full- and part-time workers. The scenic value of the watershed, measured in terms of wildlife viewing and tourism, is estimated to generate an additional $100 million per year and supports nearly 1,700 full- and part-time workers. The subsistence harvest of fish also contributes to the region’s cash economy when Alaskan households spend money on subsistence-related supplies. These contributions are estimated to be over $6 million per year. This does not include the replacement value of subsistence resources. These economic data provide background only. The economic effects of mining are not assessed.

Geological Resources

In addition to significant and valuable ecological resources, the Nushagak and Kvichak River watersheds contain considerable mineral resources. The potential for large-scale mine development in the region is greatest for copper deposits and, to a lesser extent, for intrusion-related gold deposits. Because these deposits are low-grade—meaning that they contain relatively small amounts of metals relative to the amount of ore—mining will be economic only if conducted over large areas, and mining will produce large amounts of waste material.
The largest known and most explored deposit is the Pebble deposit. If fully mined, the Pebble deposit could produce more than 11 billion tons of ore, which would make it the largest mine of its type in North America. Although the Pebble deposit represents the most imminent and likely site of mine development, other mineral deposits with potentially significant resources exist in the Nushagak and Kvichak River watersheds. Ten specific claims with more than minimal recent exploration have been filed for copper deposits, most near the Pebble deposit. Findings of this assessment concerning the impacts of large-scale mining are generally applicable to these other sites.

Mine Scenarios

Like all risk assessments, this assessment is based on scenarios that define a set of possible future activities. To assess mining-related stressors that could affect ecological resources in the watershed, we developed realistic mine scenarios that include a range of mine sizes and operating conditions. These mine scenarios are based on the Pebble deposit because it is the best-characterized mineral resource and the most likely to be developed in the near term. The mine scenarios draw on plans developed for Northern Dynasty Minerals, consultation with experts, and baseline data collected by the Pebble Limited Partnership to characterize the likely mine site, mining activities, and surrounding environment. Details of any future mine plan for the Pebble deposit or for other deposits in the watershed will differ from our mine scenarios. However, our scenarios reflect the general characteristics of mineral deposits in the watershed, modern conventional mining technologies and practices, the scale of mining activity required for economic development of the resource, and the necessary development of infrastructure to support large-scale mining. Therefore, the mine scenarios evaluated in the assessment realistically represent the type of development plan that can be anticipated for a porphyry copper deposit in the Bristol Bay watershed. Uncertainties associated with the mine scenarios are discussed later in this executive summary.

The three mine scenarios evaluated in the assessment are based on the amount of ore processed: Pebble 0.25 (approximately 0.25 billion tons [0.23 billion metric tons] of ore and duration of 20 years), Pebble 2.0 (approximately 2.0 billion tons [1.8 billion metric tons] of ore and duration of 25 years), and Pebble 6.5 (approximately 6.5 billion tons [5.9 billion metric tons] of ore and duration of 78 years). The major parameters of the three mine scenarios are presented in Table ES-1, and their layouts are presented in Figure ES-4. The largest features of a mine would be an open pit, waste rock piles, and TSFs. Other significant features include an ore-processing facility and a water collection and treatment system. An underground extension of the mine could increase the size of the mine to 11 billion tons of ore, is not included in this assessment.

The mine scenarios include a 138-km (86-mile) transportation corridor of which 113 km (70 miles) would be within the assessment watersheds (Figure ES-5). This corridor would include a gravel-surfaced road and four pipelines (one each for product concentrate, return water, diesel fuel, and natural gas).
The assessment considers risks from routine operation of a mine designed using modern conventional mitigation practices and technologies and with no significant human or engineering failures. The assessment also considers various failures that have occurred during the operation of other mines and could occur in this case, including failures of a tailings dam, pipelines, a wastewater treatment plant, and culverts.

Risks to Salmon and Other Fishes

Based on the mine scenarios, the assessment defines mining-related stressors that could affect the Bristol Bay watershed’s fishes and consequently have impacts on wildlife and human welfare. The scenarios include both routine operations (Tables ES-2 and ES-3) and several potential failure scenarios (Table ES-4).

Mine Footprint

Effects on fishes resulting from habitat loss and modification would occur directly in the area of mining activity and indirectly downstream because of habitat destruction.

- **Loss of 38, 90, and 145 km (24, 56 and 90 miles) of streams in the footprint of the mine pit, TSFs and waste rock piles, due to elimination, blockage, or dewatering of streams under the Pebble 0.25, 2.0, and 6.5 scenarios, respectively. These losses would translate to losses of 8, 24, and 35 km (5, 15, and 22 miles) of streams known to provide spawning or rearing habitats for coho salmon, sockeye salmon, Chinook salmon, and Dolly Varden. (Figure ES-6.)**

- **Altered streamflow due to retention and discharge of water used in mine operations, ore processing, transport, and other processes would reduce the amount and quality of fish habitat. Reductions in streamflow exceeding 20% would adversely affect habitat in an additional 15, 26 and 54 km (9.3, 16 and 34 miles) of streams under the Pebble 0.25, 2.0, and 6.5 scenarios, respectively, reducing production of sockeye salmon, coho salmon, Chinook salmon, rainbow trout, and Dolly Varden. Reduced flows would also result in an unquantifiable area of riparian floodplain wetland habitat being lost or altered in terms of hydrologic connectivity with streams.**

- **Loss of 5.0, 12.4 and 19.4 km² (1,200, 3,000 and 4,800 acres) of wetlands in the footprints of the Pebble 0.25, 2.0, and 6.5 scenarios, respectively, would reduce off-channel habitat for salmon and other fishes (Figure ES-6). Wetland loss would reduce availability of and access to hydraulically and thermally diverse habitats that can provide enhanced foraging opportunities and important rearing habitats for juvenile salmon.**

- **Indirect effects of stream and wetland losses would include reductions in the quality of downstream habitat for coho salmon, sockeye salmon, Chinook salmon, rainbow trout, and Dolly Varden. These indirect effects cannot be quantified, but likely would diminish fish production downstream of the mine site. Indirect effects would be caused by the following alterations.**
  - Reduced food resources would result from the loss of organic material and drifting invertebrates from the streams and streamside wetlands lost to the mine footprint.
  - The balance of surface water and groundwater inputs to downstream reaches would shift, potentially reducing winter fish habitat and making streams less suitable for spawning and rearing.
Seasonal temperatures could be altered by water treatment and reduced groundwater flowpaths, making streams less suitable for salmonids.

Water Quality

Leakage during Routine Operations

Water from the mine site could enter streams through the wastewater treatment plant discharges and in uncollected runoff and leakage of leachates from the waste rock piles and tailings storage facilities. Wastewater treatment is assumed to meet all state and national standards and criteria, or equivalent benchmarks for chemicals that have no criteria. However, water quality would be diminished by uncollected leakage of tailings and waste rock leachates from the containment system. Test leachates from the tailings and non-ore-bearing waste rocks are mildly toxic. They would require an approximately two-fold dilution to achieve water quality criteria for copper, but are not estimated to be toxic to salmonids. Waste rocks associated with the ore body are acid-forming with high copper concentrations in test leachates, and would require 2,900- to 52,000-fold dilution to achieve water quality criteria. Several metals could be sufficiently elevated to contribute to toxicity, but copper is the dominant toxicant.

Because leachates could leak during routine operations, instream copper levels would be sufficient to cause direct effects on salmonids in 29 and 57 km (18 and 35 miles) of streams beyond the mine scenario footprints in the Pebble 2.0 and Pebble 6.5 scenarios, but not in the Pebble 0.25 scenario (Table ES-2). These effects would range from aversion and avoidance of the affected habitat to rapidly induced death of many or all fish in 12 km of streams under the Pebble 6.5 scenario. Copper would cause death or reduced reproduction of aquatic invertebrates in 15, 62, and 83 km (9.3, 38, and 51 miles) of streams in the Pebble 0.25, 2.0, and 6.5 scenarios, respectively. These invertebrates are the primary food source for juvenile salmon and all life stages of other salmonids, so reduced invertebrate productivity would reduce fish productivity. These results are sensitive to the assumed efficiency of the leachate capture system, and a more efficient system could be devised. However, greater than 99% capture efficiency would be required to prevent exceedance of the copper criteria for the South Fork Koktuli River under the Pebble 6.5 scenario, which would require technologies beyond those specified in our scenarios or identified in the most recent preliminary mine plan.

Wastewater Treatment Plant Failure

Based on a review of historical and currently operating mines, some failure of water collection and treatment systems would be likely during operation or post-closure periods. A variety of water collection and treatment failures are possible, ranging from operational failures resulting in short-term releases of untreated or partially treated leachates to long-term failures to operate water collection and treatment systems in perpetuity. A reasonable upper bound failure scenario would involve a complete loss of water treatment and release of untreated wastewater. Under that scenario, copper concentrations would be sufficient to cause direct effects on salmonids in 45, 100, and 100 km (28, 63, and 64 miles) of streams and on aquatic invertebrates in 100, 110, and 130 km (62, 68, and 80 miles) of
 streams in the Pebble 0.25, 2.0, and 6.5 scenarios, respectively (Table ES-2). Under the Pebble 6.5 scenario, death of fish would occur rapidly in 31 km (19 miles) of stream following treatment failure, but effects on fish would be less severe in the other scenarios.

**Transportation Corridor**

**Construction and Routine Operation**

In the Kvichak River watershed, the transportation corridor would cross 53 streams and rivers known or likely to support migrating and resident salmonids, including 20 streams designated as anadromous waters at the location of the crossing (Figure ES-7). The corridor would run near Iliamna Lake and cross multiple tributary streams near their confluence with the lake. These habitats are important spawning areas for sockeye salmon, putting sockeye particularly at risk from the road. Diminished habitat quality in streams and wetlands below road crossings would result primarily from altered flow, runoff of road salts, and siltation of habitat for salmon spawning and rearing and production of invertebrate prey (Tables ES-2 and ES-3).

**Culvert Failures**

The most likely serious failure associated with the road would be blockages or other failures of culverts that would inhibit fish passage. Culverts commonly become blocked by debris or ice that may not stop water flow but create a barrier to fish movement. Fish passage may also be blocked or inhibited by erosion below a culvert that “perches” the culvert, resulting in a waterfall, or by shallow water caused by a wide culvert and periodic low stream flows. If blockages occurred during adult salmon immigration or juvenile salmon emigration and were not cleared for several days, production of a year-class (i.e., fish spawned in the same year) could be lost or diminished from that stream above the culvert.

Culverts can also fail to convey water as a result of landslides or, more commonly, floods that wash out culverts that are too small or improperly installed. In such failures, the stream could be temporarily impassible to fish until the culvert is repaired or until erosion re-establishes the channel. If the failure occurs during a critical period in salmon migration, the effects would be the same as with a debris blockage (i.e., a lost or diminished year-class).

Culvert failures also could result in the downstream transport and deposition of silt, which could cause returning salmon to avoid a stream if they arrived during or immediately following the failure. More likely, deposition of silt would smother salmon eggs and alevins, if they were present, and would degrade downstream habitat for salmonids and the invertebrates that they eat.

Extended blockage of fish passage at road crossings is unlikely during operation in our scenarios, which specify daily inspection and maintenance. However, after mine operations cease, the road may be maintained less carefully by the operator or may be transferred to a government entity that likely would not be able to support daily inspection and maintenance. In either case, the proportion of culverts that are impassible would be expected to revert to levels found in published surveys of public roads (range of 30 to 58%, mean of 47%). Of the approximately 46 culverts that would be required, 35 would be on
streams that are believed to support salmonids. Hence, over the long term, 10 to 20 streams would be expected to lose passage of salmon, rainbow trout, or Dolly Varden for an indefinite period of time, and some proportion of those streams would have degraded downstream habitat resulting from sedimentation from washout of the road.

**Truck Accidents**

Trucks would carry ore processing chemicals to the mine site. Truck accidents are likely over the long period of mine operation and could release process chemicals to streams, resulting in toxic effects on invertebrates or fish. The risk of spills might be mitigated by using impact-resistant containers.

**Tailings Dam Failure**

Tailings are the waste materials produced during ore processing, which, in our scenarios, would be stored in TSFs consisting of tailings dams and impoundments. The probability of a tailings dam failure increases with the number of dams. The Pebble 0.25 scenario would include one TSF with a single dam, the Pebble 2.0 scenario would include one TSF with three dams, and the Pebble 6.5 scenario would include three TSFs with a total of nine dams. Because there is no plan for their removal when mining activities cease, the TSFs and their component dams are likely to be in place for hundreds to thousands of years, long beyond the life of the mine. Available reports from the PLP suggest tailings dams as high as 209 m (685 feet) at TSF 1. At this height, the tailings dam would be higher than the St. Louis Gateway Arch and the Washington Monument (Figure ES-8). We evaluated two potential dam failures in this assessment: one when TSF 1 was partially full (under the Pebble 0.25 scenario) and one when it was completely full (under the Pebble 2.0 scenario). In both cases we assumed 20% of the tailings would be released, a conservative estimate that is well within the range of historical tailings dam failures. Failures in the Pebble 6.5 scenario, which includes three TSFs, were not analyzed but would be similar.

| Table ES 2. Summary of estimated stream lengths potentially affected under the three mine scenarios, assuming routine operations. |
| Effect | Stream Length Affected (km) |
| --- | --- | --- | --- |
| | Pebble 0.25 | Pebble 2.0 | Pebble 6.5 |
| Eliminated, blocked, or dewatered | 38 | 90 | 145 |
| Eliminated, blocked, or dewatered—anadromous | 8 | 24 | 35 |
| >20% flow reduction<sup>a</sup> | 15 | 26 | 54 |
| Direct toxicity to fish<sup>a</sup> | 0 | 29 | 57 |
| Direct toxicity to invertebrates<sup>a</sup> | 15 | 62 | 83 |
| Downstream of transportation corridor | 290 |

<sup>a</sup> Stream reaches with flow reductions partially overlap those with toxicity.
### Table ES 3. Summary of estimated wetland areas potentially affected under the three mine scenarios, assuming routine operations.

### Table ES 4. Probability and consequences of potential failures under the mine scenarios.

<table>
<thead>
<tr>
<th>Failure Type</th>
<th>Probability&lt;sup&gt;a&lt;/sup&gt;</th>
<th>Consequences</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tailings dam</td>
<td>4 x 10⁻⁴ to 4 x 10⁻⁶ per dam-year = recurrence frequency of 2,500 to 250,000 years&lt;sup&gt;b&lt;/sup&gt;</td>
<td>More than 30 km of salmonid stream would be destroyed and more streams and rivers would have greatly degraded habitat for decades.</td>
</tr>
<tr>
<td>Product concentrate pipeline</td>
<td>10⁻³ per km-year = 95% chance per pipeline in 25 years</td>
<td>Most failures would occur between stream or wetland crossings and might have little effect on fish.</td>
</tr>
<tr>
<td>Concentrate spill into a stream</td>
<td>1.5 x 10⁻² per year = 1 to 2 stream-contaminating spills in 78 years</td>
<td>Fish and invertebrates would experience acute exposure to toxic water and chronic exposure to toxic sediment in a stream and potentially extending to Iliamna Lake.</td>
</tr>
<tr>
<td>Concentrate spill into a wetland</td>
<td>3 x 10⁻² per year = 2 wetland-contaminating spills in 78 years</td>
<td>Invertebrates and potentially fish would experience acute exposure to toxic water and chronic exposure to toxic sediment in a pond or other wetland.</td>
</tr>
<tr>
<td>Return water pipeline</td>
<td>Same as product concentrate pipeline</td>
<td>Fish and invertebrates would experience acute exposure to toxic water.</td>
</tr>
<tr>
<td>Diesel pipeline spill</td>
<td>Same as product concentrate pipeline</td>
<td>Acute toxicity would reduce the abundance and diversity of invertebrates and possibly cause a fish kill if spilled to a stream or wetland.</td>
</tr>
<tr>
<td>Culvert, during operation</td>
<td>Low</td>
<td>Frequent inspections and regular maintenance would result in few impassable culverts.</td>
</tr>
<tr>
<td>Culvert, post-operation</td>
<td>3 x 10⁻¹ to 6 x 10⁻² per culvert; instantaneous = 11 to 21 culverts</td>
<td>If culvert failures revert to those seen in surveys of roads, 11 to 21 salmonid streams would have impeded fish passage.</td>
</tr>
<tr>
<td>Truck accidents</td>
<td>1.9 x 10⁻⁷ spills per mile of travel = 4 accidents in 25 years (up to 2 near-stream spills in 78 years)</td>
<td>Accidents that spill processing chemicals into a stream or wetland could cause a fish kill.</td>
</tr>
<tr>
<td>Water collection and treatment, operation</td>
<td>0.60 to 0.93 = proportion of recent U.S. mines with reportable water collection and treatment failures. Better practices might reasonably be expected to reduce this to 0.1.</td>
<td>Water collection and treatment failures are very likely to result in exceedance of standards potentially including death of fish and invertebrates, but not necessarily as severe or extensive as in the failure scenario.</td>
</tr>
<tr>
<td>Water collection and treatment, managed post-closure</td>
<td>Somewhat higher than operation</td>
<td>Collection and treatment failures are highly likely to result in release of untreated or incompletely treated leachates for days to months, but the water would be less toxic due to elimination of PAG waste rock.</td>
</tr>
<tr>
<td>Water collection and treatment, after site abandonment</td>
<td>Certain</td>
<td>When water is no longer managed, untreated leachates would flow to the streams. However, the water would be less toxic due to elimination of PAG waste rock.</td>
</tr>
</tbody>
</table>

<sup>a</sup> Because of differences in derivation, the probabilities are not directly comparable.

<sup>b</sup> Based on expected state safety requirements. Observed failure rates for earthen dams are higher (about 5 x 10⁻⁴ per year or a recurrence frequency of 2,000 years).
Figure ES 6. Streams and wetlands lost (eliminated, blocked, or dewatered) under the Pebble 6.5 scenario. Blue areas indicate streams and lakes from the National Hydrography Dataset and wetlands from the National Wetlands Inventory.
Figure ES 7. Salmon, Dolly Varden, and rainbow trout distribution along the transportation corridor. Designation of salmon presence is based on the Anadromous Waters Catalog; designation of Dolly Varden and rainbow trout presence is based on the Alaska Freshwater Fish Inventory.

Note: Sampling intensity is greatly reduced away from the Pebble deposit area. Streams without data points may not have been surveyed; thus, it is unknown whether or not they provide suitable habitat for this species.
The range of estimated probabilities of dam failure is wide, reflecting the great uncertainty concerning such failures. The most straightforward method of estimating the annual probability of a tailings dam failure is to use the historical failure rate of similar dams. Three reviews of tailings dam failures produced an average rate of approximately 1 failure per 2,000 dam years, or $5 \times 10^{-4}$ failures per dam year. The argument against this method is that the record of failure does not fully reflect current engineering practice. Some studies suggest that improved design, construction, and monitoring practices can reduce the failure rate by an order of magnitude or more, resulting in an estimated failure probability within the range assumed here. The State of Alaska’s guidelines suggest that an applicant follow accepted industry design practices such as those provided by the U.S. Army Corps of Engineers (USACE), the Federal Energy Regulatory Commission (FERC), and other agencies. Based on safety factors in USACE and FERC guidance, we estimate that the probability of failure for all causes requires a minimum factor of safety of 1.5 against slope instability, for the loading condition corresponding to steady seepage from the maximum storage facility. An assessment of the correlation of dam failure probabilities with slope instability safety factors suggests an annual probability of failure of 1 in 250,000 per year for facilities designed, built, and operated with state-of-the-practice engineering (Category I facilities) and 1 in 2,500 per year for facilities designed, built, and operated using standard engineering practice (Category II facilities). The advantage of this approach is that it addresses current regulatory guidelines and engineering practices. The disadvantage is that we do not know whether standard practice or state-of-the-practice dams will perform as expected, particularly given the potentially large size of tailings dams and subarctic conditions in these scenarios.
Failure of the dam at TSF 1 (the only TSF in all three mine scenarios) would result in the release of a flood of tailings slurry into the North Fork Koktuli River, scouring the valley and depositing many meters of tailings fines in a sediment wedge across the entire valley near the TSF dam, with lesser quantities of fines deposited at least as far as the North Fork’s confluence with the South Fork Koktuli River. The North Fork Koktuli River currently supports spawning and rearing populations of sockeye, coho, and Chinook salmon; spawning populations of chum salmon; and rearing populations of Dolly Varden and rainbow trout. The tailings slurry flood would continue down the mainstem Koktuli River with similar effects, the extent of which cannot be estimated at this time due to model and data limitations.

The tailings dam failures evaluated in the assessment would be expected to have the following severe direct and indirect effects on aquatic resources, particularly salmonids.

- **It is very likely that the North Fork Koktuli River below the TSF 1 dam and much of the mainstem Koktuli River would not support salmonids in the short term (less than 10 years).**
  - There would be a complete loss of suitable salmon habitat in the North Fork Koktuli River along at least 30 km (18.6 miles) of stream habitat, which was the spatial limit of the modeling conducted for this assessment.
  - Deposited tailings would degrade habitat quality for both fish and the invertebrates they eat. Based largely on their copper content, deposited tailings would be toxic to benthic macroinvertebrates, but existing data concerning toxicity to fish are less clear.
  - Deposited tailings would continue to erode from the North Fork Koktuli River and mainstem Koktuli River valleys.
  - Suspension and redeposition of tailings would likely cause serious habitat degradation in the mainstem Koktuli River and downstream into the Mulchatna River; however, the extent of these effects cannot be estimated at this time due to model and data limitations.

- **The affected streams would provide low-quality spawning and rearing habitat for a period of decades.**
  - Recovery of suitable substrates via mobilization and transport of tailings would take years to decades, and would affect much of the watershed downstream of the failed dam.
  - Ultimately, spring floods and stormflows would carry some proportion of the tailings into the Nushagak River.
  - For some years, periods of high flow would be expected to suspend sufficient concentrations of tailings to cause avoidance, reduced growth and fecundity, and even death of fish.
Near-complete loss of North Fork Koktuli River fish populations would likely result from these habitat losses.

- The Koktuli River watershed is an important producer of Chinook salmon. The Nushagak River watershed, of which the Koktuli River watershed is a part, is the largest producer of Chinook salmon in the Bristol Bay region, with annual runs averaging over 190,000 fish.

- A tailings spill would be expected to eliminate 25% or more of the Chinook salmon run in the Nushagak River due to loss of the Koktuli River watershed population; an additional 10 to 20% could be lost due to tailings deposited in the Mulchatna River and its tributaries.

- Sockeye are the most abundant salmon returning to the Nushagak River watershed, with annual runs averaging more than 1.9 million fish. The proportion of sockeye and other salmon species of Koktuli-Mulchatna origin is unknown.

- Similarly, the North Fork Koktuli River populations of rainbow trout and Dolly Varden would be lost for years to decades if they could not be successfully maintained entirely in headwater networks upstream of the affected zone. Quantitative estimates of these losses are not possible given available information.

Effects would be qualitatively similar for both the Pebble 0.25 and Pebble 2.0 dam failures, although effects from the Pebble 2.0 dam failure would extend farther and last longer. Failure of dams at the two additional TSFs under the Pebble 6.5 scenario (TSF 2 and TSF 3) were not modeled, but would have similar types of effects in the South Fork Koktuli River and downstream rivers.

**Pipeline Failures**

Under the mine scenarios, the primary mine product would be a copper concentrate with traces of other metals that would be pumped in a pipeline to a port on Cook Inlet. Water that carried the sand-like concentrate would be returned to the mine site in a second pipeline. Based on the general record of pipelines and further supported by the record of metal concentrate pipelines at existing mines, one to two near-stream failures of each of these pipelines would be expected to occur over the life of the Pebble 6.5 scenario (approximately 78 years). Failure of either the product or the return water pipeline would release water that is expected to be highly toxic due to dissolved copper with potential contributions to toxicity by processing chemicals. Invertebrates, and potentially early life stages of fish, would be killed in the affected stream over a relatively brief period. If concentrate spilled into a stream, it would settle and form highly toxic bed sediment based on its high copper content and acid generation. The mean velocities of many streams crossed by the pipelines are sufficient to carry the concentrate downstream to Iliamna Lake, but some would collect in low-velocity areas of the receiving stream. If the spill occurred during low flows, dredging could recover some concentrate but would cause physical damage to the stream. Concentrations in Iliamna Lake could not be predicted, but near the pipeline route, Iliamna Lake contains important beach spawning areas for sockeye salmon that could be exposed to a toxic spill. Sockeye also spawn in the lower reaches of streams that could be directly contaminated by a spill.
The diesel fuel pipeline also would be expected to spill near a stream over the life of the mine. Based on evidence from modeling the dissolved and dispersed oil concentrations in streams, laboratory tests of diesel toxicity, and studies of actual spills in streams, a diesel spill at a stream crossing would be expected to kill invertebrates and probably fish as well. Remediation would be difficult and recovery would likely take 1 to 3 years. Failure of the natural gas pipeline would also be likely, but significant effects on fish are unlikely.

Common Mode Failures

Multiple, simultaneous failures could occur as a result of a common event, such as a severe storm with heavy precipitation (particularly one that fell on spring snow cover) or a major earthquake. Over the long period that tailings impoundments, a mine pit, and waste rock piles would be in place, the likelihood of multiple extreme precipitation events, earthquakes, or combinations of these events becomes much greater. Multiple events further increase the chances of weakening and eventual failure of facilities that remain in place.

Such an event could cause multiple dam failures that would spill tailings slurry into both the South and North Fork Koktuli Rivers; road culvert washouts that would send sediments downstream and potentially block fish passage; and pipeline failures that would release product slurry, return water, or diesel fuel. The effects of each of these accidents individually would be the same as discussed previously, but their co-occurrence would cause cumulative effects on salmonid populations and make any remedial responses more difficult.

Fish-Mediated Risks to Wildlife

Although the effects of salmonid reductions on wildlife—that is, fish-mediated risks to wildlife—cannot be quantified given available data, some reduction in wildlife would be expected under the mine scenarios. Changes in the occurrence and abundance of salmon have the potential to change animal behavior and reduce wildlife population abundances. The mine footprints would be expected to have local effects on brown bears, wolves, bald eagles, and other wildlife that consume salmon, as a result of reduced salmon abundance from the loss and degradation of habitat in or immediately downstream of the mine footprint. Any of the accidents or failures evaluated would increase effects on salmon, which would further reduce the abundance of their predators.

The abundance and production of wildlife also is enhanced by the marine-derived nutrients that salmon carry upstream on their spawning migration. These nutrients are released into streams when the salmon die, enhancing the production of other aquatic species that feed wildlife. Salmon predators deposit these nutrients on the landscape, thereby fertilizing terrestrial vegetation, which, in turn, provides food for moose, caribou, and other wildlife. The loss of these nutrients from a reduction in salmon would likely reduce the production of riparian or upland species.
**Fish-Mediated Risks to Alaska Native Cultures**

Under routine operations with no major accidents or failures, the predicted loss and degradation of salmonid habitat in South and North Fork Koktuli Rivers and Upper Talarik Creek would be expected to have some impact on Alaska Native cultures of the Bristol Bay watershed. Fishing and hunting practices are expected to change in direct response to the stream, wetland, and terrestrial habitats lost to the mine footprints and the transportation corridor. It is also possible that subsistence use of salmon resources could decline based on the perception of reduced fish or water quality resulting from mining.

The potential for significant effects on Alaska native cultures is much greater from mine failures that would reduce or eliminate fish populations in affected areas, including areas significant distances downstream from the mine. In the case of the TSF failures described in the assessment, the significant loss of Chinook salmon populations would have severe consequences, especially for villages in the Nushagak River watershed.

Any loss of fish production from these failures would reduce the availability of these subsistence resources to local Alaska Native villages, and the reduction of this highly nutritious food supply could have negative consequences on human health. Because salmon-based subsistence is integral to Alaska Native cultures, the effects of salmon losses go beyond loss of a food resource. If salmon quality or quantity was adversely affected (or perceived to be affected), the nutritional, social, and spiritual health of Alaska Natives and their culture would decline.

**Cumulative Risks**

This assessment has focused on the effects of a large mine at a single deposit on salmon and other resources in the Nushagak and Kvichak River watersheds, including the cumulative effects of multiple stressors associated with that mine. However, multiple mines and associated infrastructure may be developed in these watersheds. Each mine would pose risks similar to those identified in the mine scenarios. Estimates of the stream and wetland habitats lost would differ across different deposits, based on the size and location of mine operations within the watersheds. Individually, each mine footprint would eliminate some amount of fish-supporting habitat and, should operator or engineering failures occur, affect fish habitats well beyond the mine footprint.

We considered development of mines at several sites in the Nushagak River watershed, including the Pebble South/PEB, Big Chunk South, Big Chunk North, Groundhog, AUDN/Iliamna, and Humble claims. These sites were chosen because all contain copper deposits that have generated exploratory interest. If all six mine sites were developed, the cumulative area covered by the six mine footprints could be 35 to 53 km² (8,600 to 13,000 acres). Stream habitats lost to eliminated or blocked streams could be 41 to 64 km (25 to 40 miles). Cumulative wetland losses could be 7.4 to 25 km² (1,800 to 6,100 acres).

These are conservative estimates of lost habitats, because we did not estimate the hydrologic drawdown zones around each mine pit as was done for the Pebble scenarios. Inclusion of the drawdown area in the
Pebble 0.25 scenario increased the area of stream and wetlands losses by 84%. A similar increase might be expected at the other mine sites, depending on local geology.

In addition, mine operations are assumed to be of average size, and would modify flows and diminish water quality to approximately the same extent as the Pebble 0.25 scenario. Waters on these claim blocks include the Chulitna River and Rock, Jensen, Yellow, Napotoli, Klutuk, and Kenakuchuk Creeks, as well as over 250 unnamed tributaries and over 50 unnamed lakes and ponds. Although not all support salmon, many do. Loss of substantial habitat across the watersheds could contribute to diminishing the genetic diversity of salmon stocks and thereby increasing annual variability in salmon returns.

**Mitigation and Remediation**

The mine scenarios assessed here include modern conventional mitigation practices as reflected in Northern Dynasty Mineral’s published plan for the Pebble deposit, plus practices suggested in the mining literature and consultations with experts. These practices include, but are not limited to, processing all potentially acid-generating waste rock before closure, managing effluent water temperatures, inspecting and maintaining roads daily, and providing automatic monitoring and remote shut-off for the pipelines. However, we recognize that risks could be further reduced by unconventional or even novel mitigation measures, such as dry stack tailings disposal or the use of armored tanks on the trucks carrying process chemicals to the site. These practices may be unconventional because they are expensive, unproven, or impractical. However, these obstacles to implementation might be overcome, as justified by the large mineral resource and the highly valued natural and cultural resources of the Bristol Bay watershed.

Although remediation would be considered if spills contaminated streams, features of the Pebble deposit area would make remediation difficult. Pipeline crossings of streams would be near Iliamna Lake, so the time available to block or collect spilled material would be short. Spilled return water and the aqueous phase of the product concentrate slurry would be unrecoverable. The product concentrate itself would resemble fine sand, and mean velocities in many receiving streams would be sufficient to suspend and transport it. Hence, concentrate spilled or washed into streams could be recovered only where it collected in low-velocity locations. Diesel spills would dissolve, vaporize, and flow as a slick to Iliamna Lake. Booms and absorbents are not very effective in moderate- to high-velocity streams. Spilled tailings from a dam failure would flow into streams, rivers, and floodplains that are in roadless areas and not large enough to float a barge-mounted dredge. Recovery, transport, and disposal of hundreds of millions of metric tons of tailings under those conditions would be extremely difficult and would result in additional environmental damage. Compensatory mitigation measures could offset some of the stream and wetland losses, although there are substantial challenges regarding the efficacy of these measures to offset adverse impacts.
Summary of Uncertainties in Mine Design and Operation

This assessment considers realistic mine scenarios that are based on specific characteristics of the Pebble deposit and plans proposed by Northern Dynasty Minerals and are generally applicable to copper deposits in the Bristol Bay watershed. If the Pebble deposit is mined, actual events will undoubtedly deviate from these scenarios. This is not a source of uncertainty, but rather an inherent aspect of a predictive assessment. Even an environmental assessment of a specific plan proposed for permitting by a mining company would be an assessment of a scenario that undoubtedly would differ from the actual development.

Multiple uncertainties are inherent in planning, designing, constructing, operating, and closing a mine. These uncertainties, summarized below, are inherent in any complex enterprise, particularly when that enterprise involves an incompletely characterized natural system. However, the large scales and long durations required of mining the Pebble deposit make these inherent uncertainties more prominent.

- Mines are complex systems requiring skilled engineering, design, and operation. The uncertainties facing mining and geotechnical engineers include unknown geologic features, uncertain values in geological properties, limited knowledge of mechanisms and processes, and human error in design and construction. Models used to predict the behavior of engineered systems represent idealized processes, and by necessity contain simplifications and approximations that potentially introduce errors.

- Accidents are unplanned and inherently unpredictable. Although systems can be put into place to protect against system failures, seemingly logical decisions about how to respond to a given situation can have unexpected consequences due to human error (e.g., the January 2012 overflow of the tailings dam at the Nixon Fork Mine near McGrath, Alaska). Further, unforeseen events or events that are more extreme than anticipated can negate apparently reasonable operation and mitigation plans.

- The ore deposit would be mined for decades, and wastes would require management for centuries or even in perpetuity. Engineered waste storage systems of mines have been in existence for only about 50 years and their long-term behavior is not known. The response of the current technology in the construction of tailings dams is untested and unknown in the face of centuries of extreme events such as earthquakes and weather.

- Mine management or ownership may change over time. Over the long time span (centuries) of mining and post-mining care, generations of mine operators must exercise due diligence. Priorities are likely to change in the face of financial circumstances, changing markets for metals, new information about the resource, political priorities, or any number of currently unforeseeable changes in circumstance.
Summary of Uncertainties and Limitations in the Assessment

The most important uncertainties concerning estimated effects of the mine scenarios, as judged by the assessment authors, are identified below.

- Consequences of the loss and degradation of habitat on fish populations could not be quantified because of the lack of quantitative information concerning salmonid populations in freshwater habitats. The occurrence of salmonid species in rivers and major streams is known, but information on abundances, productivities, and limiting factors in each of the watersheds is not available. Estimating changes in populations would require population modeling, which requires knowledge of life-stage-specific survival and production and of the limiting factors and processes. Further, it requires knowledge of how temperature, habitat structure, prey availability, density dependence, and sublethal toxicity influence life-stage-specific survival and production. Obtaining this information would require more detailed monitoring and experimentation. Furthermore, salmon populations naturally vary in size due to many factors that vary among locations and years. At present, data are insufficient to establish reliable salmon population estimates and obtaining such data takes many years. Estimated effects of mining on fish habitat thus become the surrogate for estimated effects on fish populations.

- Standard leaching test data are available for test tailings and waste rocks from the Pebble deposit, but these results are uncertain predictors of the actual composition of leachates from tailings impoundments, tailings deposited in streams and on their floodplains, and waste rock piles.

- Capture efficiencies for leachates are uncertain. For waste rock outside of the mine pit drawdown zone, we assume 50% capture. To avoid exceeding water quality criteria for copper, more than 99% capture would be required.

- The effects of tailings and product concentrate deposited in spawning and rearing habitat are uncertain. It is clear that they would have harmful physical and toxicological effects on salmonid larvae or sheltering juveniles, but the concentration in spawning gravels required to reduce salmonid reproductive success is unknown.

- The estimated annual probability of tailings dam failure is uncertain because it is based on design goals. Historical experience is presumed to provide an upper bound. Features that should reduce failure frequencies have not been tested for the thousands of years that they must function properly. Hence, actual failure rates could be higher or lower than the estimated probability.

- The proportion of tailings that would spill in the event of a dam failure could be larger than the largest value modeled (20%).

- The long-term fate of spilled tailings in the event of a dam failure could not be quantified. As in other cases, it is likely that tailings would erode from areas of initial deposition and move downstream over more than a decade. However, the data needed to model that process and the resources needed to develop that model are not available.
• The actual response of Alaska Native cultures to any impacts of the mine scenarios is uncertain. Interviews with village Elders and culture bearers and other evidence suggest that responses would involve more than the need to compensate for lost food, and would likely include some degree of cultural disruption. It is not possible to predict specific changes in demographics, cultural practices, or physical and mental health.

Uses of the Assessment

This assessment is a scientific investigation. It does not reflect any conclusions or judgments about the need for or scope of government action, nor does it offer or analyze options for future decisions. Rather, it is a scientific product intended to provide a characterization of the biological and mineral resources of the Bristol Bay watershed, increase understanding of the risks from large-scale mining to the fish resources, and inform future government decisions. The assessment will also better inform dialogue among interested stakeholders concerning the resources in the Bristol Bay watershed and the impacts of large-scale mining on those resources.
